Abstract. *Mode confusion* is a serious problem in aviation safety. Today's complex *avionics systems* make it difficult for pilots to maintain awareness of the actual states, or *modes*, of the flight deck automation. NASA explores how formal methods, especially *theorem proving*, can be used to discover mode confusion. The present paper investigates whether *state-exploration techniques*, e.g., *model checking*, are better able to achieve this task than theorem proving and also to compare the *verification tools* Murϕ, SMV, and Spin for the specific application. While all tools can handle the task well, their strengths are complementary.

1 Introduction

Digital system automation in the flight deck of aircraft has significantly contributed to aviation efficiency and safety. Unfortunately, the aviation community is also starting to experience some undesirable side effects as a result of the high degree of automation. Incidents and accidents in aviation are increasingly attributed to *pilot-automation interaction*. Although automation has reduced the overall pilot workload, in some instances the workload has just been re-distributed, causing short periods of very high workloads. In these periods, pilots sometimes get confused about the actual states, or *modes*, of the flight deck automation. *Mode confusion* may cause pilots to inappropriately interact with the on-board automation, with possibly catastrophic consequences.

NASA Langley explores ways to minimize the impact of mode confusion on aviation safety. One approach being studied is to identify the sources of mode confusion by *formally modeling* and *analyzing* avionics systems. The *mode logic* of a *flight guidance system* (FGS) was selected as a target system to develop this approach and to determine its feasibility. The FGS offers a realistic avionics system and has been specified in many notations and languages including CoRE [12], SCR [12], Z [6], ObjecTime [13], and PVS [2]. In the PVS [16] effort, the FGS, which is characterized by its *synchronous*, *reactive*, and *deterministic behavior*, was encoded as a finite state machine. Properties, which were identified

* This work was supported by the National Aeronautics and Space Administration under NASA Contract No. NAS1-97046 while the first author was in residence at the Institute for Computer Applications in Science and Engineering (ICASE), NASA Langley Research Center, Hampton, Virginia 23681-2199, USA.

as possible sources of mode confusion by experts in *human factors* [9], were also defined in the PVS language. These properties included *inconsistent behavior*, *ignored crew inputs*, and *indirect mode changes*. Proofs in the PVS model were undertaken to either show that a property holds or to discover conditions that preclude the property from being true. The employed style of theorem proving resembled a form of *state exploration*. Hence, the question arises whether state-exploration and *model-checking* techniques [3, 5] are better suited for the study of mode confusion.

In order to answer this question, we model and analyze the mode logic by applying three popular and publicly available *state-exploration/model-checking tools*, namely Murϕ [4, 14], SMV [11, 17], and Spin [7, 18]. Although all three tools are appropriate for the task, each one has its own strengths and weaknesses. We compare the tools regarding (1) the suitability of their languages for *modeling* the mode logic, (2) their suitability for *specifying* and *verifying* the *mode confusion properties* of interest, and (3) their ability to generate and *animate diagnostic information*. The first aspect concerns the way in which we model the example system. The second aspect refers to the adequacy of the language in which properties are encoded and also to the degree of orthogonality between system and property specifications. The third aspect is perhaps the most important one for engineers since system designs are often incorrect in early design stages.

2 Flight Guidance Systems and Mode Logics

The *FGS* is a component of the *flight control system* (cf. Fig. 1). It continuously determines the difference between the actual state of an aircraft – its position, speed, and attitude as measured by its *sensors* – and its desired state as inputted via the *crew interface* and/or the *flight management system*. In response, the FGS generates commands to minimize this difference, which the *autopilot* may translate into movements of the aircraft's *actuators*. These commands are calculated by *control law algorithms* that are selected by the *mode logic*.

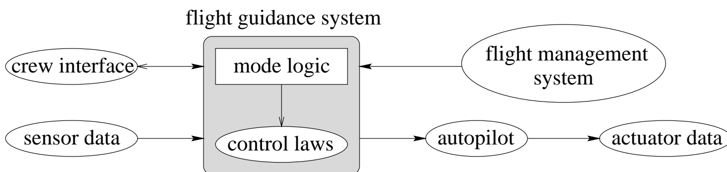

Fig. 1. Flight control system

In the following we focus on the mode-logic part of the FGS. Especially, we leave out the modeling of the control laws and, if no confusion arises, use interchangeably the terms FGS and mode logic. A mode logic essentially acts as a deterministic machine which is composed of several synchronous sub-machines.

It receives *events* from its *environment* and reacts to them by changing its state appropriately. This reaction may require several simultaneous mode changes. Fig. 2 shows a typical mode logic consisting of three interacting components: the *lateral guidance*, the *vertical guidance*, and the *flight director*. The mode of the flight director determines whether the FGS is used as a navigational aid. The lateral guidance subsumes the *roll* mode (Roll), the *heading* mode (HDG), the *navigation* mode (NAV), and the *lateral go-around* mode (LGA), whereas the vertical guidance subsumes the *pitch* mode (Pitch), the *vertical speed* mode (VS), and the *vertical go-around* mode (VGA). Each mode can be either *cleared* or *active*, with the NAV mode having additional sub-states in the *active* state.

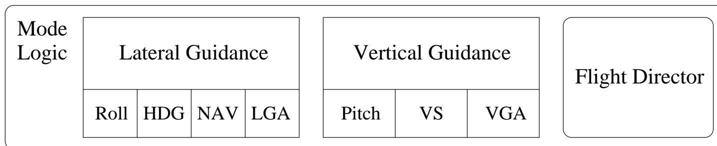

Fig. 2. Architecture of the model logic of the FGS

The properties of interest regarding the FGS can be classified as *mandatory properties* and *mode confusion properties*. Some of the mandatory properties are: (i) if the flight director is off, all lateral and vertical guidance modes must be cleared, (ii) if the flight director is on, then exactly one lateral and one vertical mode is active, and (iii) a default mode is activated when the flight director is on and other modes are cleared. Regarding mode confusion, several categories are identified in [9]. We have selected three categories to use in the analysis of our system: (1) *inconsistent behaviors*, i.e., a crew interface input has different functionality for different system states, (2) *ignored operator inputs*, i.e., a crew input does not result in a change of state, and (3) *indirect mode changes*, i.e., the system changes its state although no crew input is present. To discover sources of mode confusion, we formulate the negation of each property and try to prove it. Conditions that prevent us from successfully completing the proof – manifested by *unprovable subgoals* in a theorem prover and *error traces* in model-checking tools – are the ones we intend to uncover. This process is interactive and labor intensive when using theorem proving [13]. Thus, we investigate whether state-exploration/model-checking tools can perform the analysis more efficiently.

3 Modeling the Mode Logic in Murϕ

Murϕ [4, 14] is a state-exploration tool developed by David Dill's group at Stanford University and consists of a *compiler* and a *description language*. The compiler takes a system description and generates a C++ *special-purpose verifier* for it, which can then be used for checking *assertions* and *deadlock behavior*.

The Murϕ description language borrows many constructs found in imperative programming languages, such as Pascal. System descriptions may include declarations of *constants*, *finite data-types*, *global* and *local variables*, and unnested *procedures* and *functions*. Moreover, they contain *transition rules* for describing system behavior, a definition of the *initial states*, and a set of *state invariants* and *assertions*. Each transition rule may consist of a *guard* – which is never needed here – and an *action*, i.e., a statement which modifies global variables. A *state* in Murϕ's execution model is an assignment to all global variables in the considered description. A *transition* is determined by a rule which is chosen nondeterministically from those rules whose guards are true in the current state. The rule's execution updates some global variables according to its action.

Table 1. Specification of module *simple_guidance* in Murϕ

```
TYPE sg_modes   : ENUM { cleared, active };
TYPE sg_events  : ENUM { activate, deactivate, switch, clear };
TYPE sg_signals : ENUM { null, activated, deactivated };
PROCEDURE simple_guidance(VAR mode   : sg_modes;  event : sg_events;
                          VAR signal : sg_signals);
BEGIN
  IF mode=cleared THEN
    SWITCH event CASE activate   : signal:=activated;   mode:=active;
                 CASE deactivate : signal:=null;
                 CASE switch     : signal:=activated;   mode:=active;
                 CASE clear      : signal:=null;
    END;
  ELSE
    SWITCH event CASE activate   : signal:=null;
                 CASE deactivate : signal:=null;        mode:=cleared;
                 CASE switch     : signal:=deactivated; mode:=cleared;
                 CASE clear      : signal:=deactivated; mode:=cleared;
END; END; END;
```

The heart of the Murϕ model of the FGS is the deterministic procedure `fgs` which encodes the system's reaction to some event entering the mode logic. By declaring a transition rule for each event `env_ev` as `RULE "rule_for_env_event" BEGIN fgs(env_ev); END`, we model the nondeterministic behavior of the environment which arbitrarily chooses the event entering the system at each synchronous step. Due to space constraints we do not completely present `fgs`, but concentrate on modeling the vertical-guidance component of the FGS [10]. Let us define the modes of this component as instantiations of an abstract datatype module `simple_guidance` which encodes each mode's behavior as a simple Mealy automaton (cf. Table 1). The module is parameterized by the mode `mode` under consideration, the input event `event`, and the output event `signal`. The parameters are of enumeration types `sg_mode`, `sg_events`, and `sg_signals`, respectively. The body of `simple_guidance` specifies the reaction of a mode

to event with respect to mode. This reaction is described by an *if-statement*, two *case-selections*, and *assignments* to mode and signal. The vertical-guidance component is specified as a procedure, called vertical_guidance (cf. Table 2), and employs simple_guidance for describing the modes pitch, vs, and vga, which are defined as global variables. The task of vertical_guidance is firstly to recognize whether env_ev refers to mode Pitch, VS, or VGA. This is done by functions pitch_event, vs_event, and vga_event. Then env_ev is translated to an event of type sg_events via functions pitch_conv, vs_conv, and vga_conv, respectively, and passed to the mode to which it belongs. If this mode is activated by the event, i.e., simple_guidance returns value activated via local variable sig, then the other two modes must instantly be deactivated by invoking simple_guidance with the appropriate modes and event deactivate.

Table 2. Specification of module *vertical_guidance* in Murϕ

```
VAR pitch, vs, vga : sg_modes;
PROCEDURE vertical_guidance(env_ev:env_events);  VAR sig : sg_signals;
BEGIN CLEAR sig;
  IF  pitch_event(env_ev) THEN
    simple_guidance(pitch, pitch_conv(env_ev), sig);
    IF    sig=activated   THEN simple_guidance(vs,    deactivate, sig);
                               simple_guidance(vga,   deactivate, sig);
    END;
  ELSIF  vs_event(env_ev) THEN
    simple_guidance(vs, vs_conv(env_ev), sig);
    IF    sig=activated   THEN simple_guidance(pitch, deactivate, sig);
                               simple_guidance(vga,   deactivate, sig);
    ELSIF sig=deactivated THEN simple_guidance(pitch, activate,   sig);
    END;
  ELSIF vga_event(env_ev) THEN
    simple_guidance(vga, vga_conv(env_ev), sig);
    IF    sig=activated   THEN simple_guidance(pitch, deactivate, sig);
                               simple_guidance(vs,    deactivate, sig);
    ELSIF sig=deactivated THEN simple_guidance(pitch, activate,   sig);
END; END; END;
```

We now turn our focus to specifying mode confusion properties. As states are generated by Murϕ, assert statements, that were explicitly included in the action of a rule, are checked. If an assertion is violated – i.e., the assert statement is evaluated to false in some reachable system state – the Murϕ verifier halts and outputs diagnostic information which consists of a sequence of states leading from the initial state to the error state. The verifier also halts if the current state possesses no successor states, i.e., if it is deadlocked. Next, we show how an exemplary property of each category of the mode confusion properties mentioned in Section 2 can be stated as assertions. We encapsulate these assertions in procedure mode_confusion_properties which is invoked as the last

Table 3. Specification of some *mode confusion properties* in Murϕ

```
VAR old_pitch, old_vs, old_vga : sg_modes;
PROCEDURE mode_confusion_properties(env_ev:env_events);
BEGIN
  ALIAS mode_change : pitch!=old_pitch | vs!=old_vs | vga!=old_vga; DO
    -- check for response to pressing VS button
    IF env_ev=vs_switch_hit THEN
      assert (old_vs=cleared -> vs=active ) "vs_toggle_1";
      assert (old_vs=active  -> vs=cleared) "vs_toggle_2";
    END;
    -- search for ignored crew inputs (property violated)
    assert (crew_input(env_ev) -> mode_change)
           "search_for_ignored_crew_inputs";
    -- no unknown ignored crew inputs
    assert (crew_input(env_ev) & !ignored_crew_input(ev) -> mode_change)
           "no_unknown_ignored";
    -- search for indirect mode changes (property violated)
    assert (!crew_input(env_ev) -> !mode_change)
           "search_for_indirect_mode_changes";
    -- no unknown indirect mode changes
    assert (!crew_input(env_ev) & !indirect_mode_change(env_ev) ->
            !mode_change) "no_unknown_indirect_mode_changes";
  END;
  old_pitch:=pitch;  old_vs:=vs;  old_vga:=vga;
END;
```

statement in `fgs` (cf. Table 3). Here, "- -" introduces a comment line, `!=` denotes *inequality*, and `|`, `&`, `!`, and `->` stand for *logical disjunction*, *conjunction*, *negation*, and *implication*, respectively. Since all properties of interest concern the transition from one system state to the next, we need to store the global variables' values of the previously visited state. For this purpose we introduce new global variables `old_pitch`, `old_vs`, and `old_vga`. The need for this overhead arises because Murϕ can only reason about simple *state invariants* and not about more general "*state transition invariants*." Therefore, state transition invariants need to be encoded as state invariants, which doubles the size of the state vector for our system description. The first two assertions in Table 3, belonging to the first category of mode confusion properties, state that environment event `vs_switch_hit` acts like a toggle with respect to mode VS, i.e., if VS was in state `cleared` and `vs_switch_hit` arrived, then it is now in state `active`, and vice versa. Regarding the second category, we verify that no crew inputs are ignored, i.e., whenever an event that originated from the crew enters the mode logic, then at least one mode changes its value. We specify this property as `crew_input(env_ev) -> mode_change`, where `crew_input` is a function determining whether `env_ev` originates from the crew and where `mode_change` is a shortcut introduced as an `ALIAS` statement. As expected, this property does not always hold. The error trace returned by Murϕ helps us in identifying

the cause, as is our objective. We filter out the cause by including a predicate `ignored_crew_input`, stating the negation of the cause, in the premise of the assertion (cf. Table 3). We then re-run Murϕ and iterate this process until the assertion becomes true, thereby gradually capturing all crew-input scenarios responsible for mode confusion. Similarly, we approach the third category of mode confusion properties. The property we consider is "*no indirect mode changes*" which prohibits a system's state to change if `env_ev` is not originated by the crew. Using Murϕ, we discover the conditions that invalidate this property and, subsequently, weaken it via predicate `indirect_mode_change`. The mandatory properties mentioned in Section 2 are formalized as `invariant` statements and proved. The difference between an `assert` and an `invariant` statement is that the former appears in the system description part of the model, while the latter does not. The reason for specifying mode confusion properties in the system description is their reference to `old_pitch`, `old_vs`, and `old_vga`. In order to keep the state space small, these variables must be re-assigned to the actual values of `pitch`, `vs`, and `vga`, respectively, before a step of the synchronous system is completed.

Summarizing, Murϕ's description language turned out to be very convenient for our task since the PVS model of the FGS [13] could simply be carried over. Unfortunately, Murϕ forces us to encode state transition invariants as state invariants, thereby doubling the number of global variables and Murϕ's memory requirements. The full Murϕ model subsumes about 30 assertions and leads to a finite automaton with 242 states and 3 388 transitions. In each state, any of the 14 environment events may enter the system ("$242 \times 14 = 3\,388$"). The state-space exploration took less than 2 seconds on a SUN SPARCstation 20.

4 Modeling the Mode Logic in SMV

The SMV system [11, 17], originally developed by Ken McMillan at Carnegie-Mellon University, is a model-checking tool for verifying finite-state systems against specifications in the *temporal logic* CTL [3, 5]. SMV implements a symbolic model-checking algorithm based on *Binary Decision Diagrams* (BDDs) [1].

SMV's description language is a very simple, yet elegant language for *modularly* specifying finite-state systems, which has the feel of a *hardware description language*. The language's data types are Booleans (where *false* and *true* are encoded as `0` and `1`, respectively), enumeration types, and arrays. Its syntax resembles a style of *parallel assignments*, and its semantics is similar to single assignment *data flow languages*. In contrast to Murϕ, SMV descriptions are *interpreted*. The interpreter makes sure that the specified system is implementable by checking for *multiple assignments* to the same variable, *circular assignments*, and *type errors*. The SMV language also includes constructs for stating system specifications in the temporal logic (fair)CTL [5], which allows one to express a rich class of temporal properties, including *safety*, *liveness*, and *fairness properties*. Here, we focus on safety properties to which invariants belong.

Table 4. Specification of module *simple_guidance* in SMV

```
MODULE simple_guidance(activate, deactivate, switch, clear)
VAR    mode        :  {cleared, active};
ASSIGN init(mode)  := cleared;
       next(mode)  := case deactivated | deactivate : cleared;
                           activated                : active;
                           1                        : mode;
                      esac;
DEFINE activated   := (mode=cleared) & (activate | switch);
       deactivated := (mode=active ) & (clear    | switch);
```

A *module description* in SMV consists of four parts: (1) the `MODULE` clause, stating the module's name and its formal (call-by-reference) parameters, (2) the `VAR` clause, declaring variables needed for describing the module's behavior, (3) the `ASSIGN` clause, which specifies the initial value of all variables (cf. `init`) and how each variable is updated from state to state (cf. `next`), and (4) the `DEFINE` clause, which allows one to introduce abbreviations for more complex terms. The main module `MAIN` of our SMV specification encodes the environment of the FGS, which nondeterministically sends events to the mode logic. This is done by defining variable `env_ev` of enumeration type `env_events`, which contains all environment events, and by adding "`init(env_ev):=env_events; next(env_ev):=env_events`" to the `ASSIGN` clause. Similar to the Murϕ model, we specify a module `simple_guidance` (cf. Table 4) and, thereby, show how Mealy machines may be encoded in SMV. Module `simple_guidance` takes the input events `activate`, `deactivate`, `switch`, and `clear` – which can be either absent or present – as parameters. The state associated with `simple_guidance` is variable `mode` which may adopt values `cleared` and `active`. The initial value `init(mode)` of `mode` is `cleared`. The behavioral part of `simple_guidance` is described in the `next(mode)` statement consisting of a `case` expression. The value of this expression is determined by the first expression on the right hand side of the colon such that the condition on the left hand side is true. The symbols `=`, `&`, and `|` stand for *equality*, *logical conjunction*, and *logical disjunction*, respectively. The terms `activated` and `deactivated`, whose values are accessible from outside the module, are defined in the `DEFINE` clause.

Before we model module `vertical_guidance`, we comment on why we have encoded the input event of `simple_guidance` using four different signal lines instead of a single event of some enumeration type subsuming all four values. When `activate`, `deactivate`, `switch`, and `clear` are combined in an enumeration type, we need to identify the value of the input event via a SMV `case` construct. This induces a circularity which would be detected by the SMV interpreter, i.e., our description of the mode logic would be rejected. One difference between `simple_guidance` as a *module* in SMV and as an *abstract data-type* in Murϕ is that the mode variable is encapsulated within the SMV module and is not a call-by-reference parameter. The behavior of each mode of `vertical_guidance`, Pitch, VS, and VGA, can now be described by instantiating `simple_guidance`,

Table 5. Specification of module *vertical_guidance* in SMV

```
MODULE vertical_guidance(vs_pitch_wheel_changed, vs_switch_hit,
          ga_switch_hit, sync_switch_pressed,    ap_engaged_event)
VAR pitch : simple_guidance(pitch_activate, pitch_deactivate, 0, 0);
    vs    : simple_guidance(0, vs_deactivate, vs_switch_hit, 0);
    vga   : simple_guidance(0, vga_deactivate, ga_switch_hit, vga_clear);
DEFINE
  pitch_activate   := (vs_switch_hit & vs.deactivated) | (vga_event &
                        vga.deactivated) | vs_pitch_wheel_changed;
  pitch_deactivate := (vs_switch_hit & vs.activated) |
                        (vga_event & vga.activated);
  vs_deactivate    := (vs_pitch_wheel_changed & pitch.activated) |
                        (vga_event & vga.activated);
  vga_deactivate   := (vs_pitch_wheel_changed & pitch.activated) |
                        (vs_switch_hit & vs.activated);
  vga_clear   := ap_engaged_event | sync_switch_pressed;
  vga_event   := ap_engaged_event | sync_switch_pressed | ga_switch_hit;
```

as is done in the `VAR` clause in Table 5. Thereby, global variables `pitch.mode`, `vs.mode`, and `vga.mode` are created as part of the state vector of our SMV model. All actual parameters of each `simple_guidance` module can be specified as terms on the input parameters of `vertical_guidance`. Note that the functions `pitch_event`, `vs_event`, and `vga_event` used in the Murϕ description are encoded here in the `DEFINE` clause. Our modeling of `vertical_guidance` is self-explanatory and visualizes the differences between the SMV and the Murϕ languages. While in Murϕ each synchronous step of the FGS can be modeled by a *sequential algorithm*, it must be described by *parallel assignments* in SMV.

Table 6. Specification of some *mode confusion properties* in SMV

```
DEFINE mode_change :=
  !(vertical.pitch.mode=cleared <-> AX vertical.pitch.mode=cleared) |
  !(vertical.pitch.mode=active  <-> AX vertical.pitch.mode=active ) | ...
-- check for response to pressing VS button
SPEC AG (vertical.vs.mode=cleared & env_ev=vs_switch_hit ->
         AX vertical.vs.mode=active)
SPEC AG (vertical.vs.mode=active  & env_ev=vs_switch_hit ->
         AX vertical.vs.mode=cleared)
-- search for ignored crew inputs (property violated)
SPEC AG (crew_input -> mode_change)
-- no unknown ignored crew inputs
SPEC AG (crew_input & !ignored_crew_input -> mode_change)
-- search for indirect mode changes (property violated)
SPEC AG (!crew_input -> !mode_change)
-- no unknown indirect mode changes
SPEC AG ((!crew_input & !indirect_mode_change) -> !mode_change)
```

In SMV, temporal system properties are specified in the *Computational Tree Logic* (CTL) [3, 5] and may be introduced by the keyword `SPEC` within the same file as the system description. The properties of interest to us can be specified as CTL formulas of the form `AG`ϕ, where `AG` stands for "`always generally`," i.e., every reachable state satisfies property ϕ. The formula `AX`ϕ expresses that all successor states of the current state satisfy ϕ. In this light, the first formula in Table 6 states: "every reachable state satisfies that, if mode VS in `vertical_guidance` is currently `cleared` and event `vs_switch_hit` enters the system, then VS is `active` in every successor state of the current state." The symbols `->` and `<->` used in Table 6 stand for *logical implication* and *equivalence*, respectively. The identifiers `mode_change`, `crew_input`, `indirect_mode_change`, and `ignored_crew_input` are abbreviations of expressions defined in a `DEFINE` clause, as exemplary shown for `mode_confusion`. The presence of operator `AX` in CTL remedies the need to keep track of old values of mode variables. Thereby, the size of the associated state vector of the SMV model is cut in half when compared to the Murϕ model. Moreover, an orthogonal treatment of model and property specifications is achieved. The SMV system verified about thirty assertions in slightly more than half a second using 438 BDD nodes and allocated less than 1 MByte memory on a SUN SPARCstation 20. The properties "*search for ignored crew inputs*" and "*search for indirect mode changes*" were invalidated as in the Murϕ model. The returned error traces, including the assignments of each variable in every state of the traces, supported the identification of potential problems with the FGS model. SMV also includes an *interactive mode* which provides a very simple assistant for interactive debugging. The state space of the SMV model consists of 3 388 states, which corresponds to the 242 states of the Murϕ model since the actual environment event, out of 14 possible events, must be stored in a variable in SMV ("$242 \times 14 = 3\,388$").

Summarizing, SMV performed well for our example. CTL supports the convenient specification of mode confusion properties. However, SMV's system description language is not high-level when compared to Murϕ.

5 Modeling the Mode Logic in Spin

Last, but not least, we explore the utility of the verification tool Spin [7, 8, 18], which was developed by Gerard Holzmann at Bell Labs, for our case study. Spin is designed for analyzing the logical consistency of *concurrent systems*. It is especially targeted towards distributed systems, such as communication protocols. The system description language of Spin, called Promela, allows one to specify *nondeterministic processes*, *message channels*, and *variables* in a C-like syntax. Given a Promela description, whose semantics is again defined as a finite automaton, Spin can perform random or interactive *simulations* of the system's execution. Similar to Murϕ, it can also generate a special-purpose verifier in form of a C-program. This program performs an exhaustive exploration of the system's state space and may check for *deadlocks* and *unreachable code*, validate *invariants*, and verify properties specified in a *linear temporal logic* [5].

Table 7. Specification of the main process *init* in Spin

```
init{ env_ev=null; do :: atomic{
        if                          /* body encodes 1 synchr. step    */
        :: env_ev=vs_switch_hit     /* nondet. choice of env. event   */
        :: ...                      /* 14 cases, for each env. event  */
        fi; fgs(env_ev); env_ev=null /* perform synchronous step      */
      od }
```

Since our FGS is a synchronous system, it falls out of the intended scope of Spin. Nevertheless, we show that Spin allows us to successfully carry out our case study. The Promela fragment depicted in Table 7 encodes the main process, referred to as `init` in Spin, which is the only process of our model. Here, the global variable `env_ev` is of type `mtype` which contains an enumeration of all event and signal names that occur in the mode logic. Promela's type system supports basic data types (such as `bit`, `bool`, and `byte`), as well as arrays, structures (i.e., records), and channels. Unfortunately, one may only introduce a single declaration of enumeration type, which must be named `mtype`. The statement `atomic` in `init` attempts to execute all statements in its body in one *indivisible* step. Especially, it prevents Spin from storing intermediate states which might arise when executing the body. Thus, we may use this construct for encoding the complex algorithm of the mode logic that performs a single synchronous step. The *repetition statement* `do` together with the *choice statement* `if` nondeterministically chooses which environment event to assign to `env_ev`. The reason that we have not simply spelled out `fgs(vs_switch_hit)`, and so on for each environment event, is that `fgs` needs to be implemented as an *inline*. Expanding this long inline fourteen times turns out to be inefficient.

Table 8. Specification of module *simple_guidance* in Spin

```
inline simple_guidance(mode, event, signal)
{ if :: mode==cleared ->
          if :: event==activate   -> signal=activated;   mode=active
             :: event==deactivate -> signal=null
             :: event==switch     -> signal=activated;   mode=active
             :: event==clear      -> signal=null
          fi
     :: mode==active  ->
          if :: event==activate   -> signal=null
             :: event==deactivate -> signal=null;        mode=cleared
             :: event==switch     -> signal=deactivated; mode=cleared
             :: event==clear      -> signal=deactivated; mode=cleared
          fi
  fi }
```

Promela does not possess any kind of procedure construct other than the process declaration `proctype`. However, we may not introduce additional processes to the main process `init`, since then our model would not reflect a synchronous system any more. The only construct of Promela, which we can use for resembling the architecture of the FGS, is `inline`. This construct may take parameters, such as `mode`, `event`, and `signal` for component `simple_guidance` (cf. Table 8). When compiling a Promela description, each occurrence of `simple_guidance` in `vertical_guidance` is replaced with its body. The modes instantiating parameter `mode` are global variables of type `bit`, where `cleared` and `active` are defined as constants `0` and `1`, respectively, using the preprocessor command `#define`. The body of `simple_guidance` contains the Promela statement `if`. Its behavior is defined by a nondeterministic selection of one of its executable options, which are separated by double colons, and by executing it. In our case, each option consists of a guarded expression which is executable if the expression on the left of `->` evaluates to true in the current system state and which returns the result of evaluating the expression on the right hand side. The symbols `==` and `=` denote the *equality* and the *assignment* operator, respectively. Using `simple_guidance`, we can specify component `vertical_guidance` as another `inline` (cf. Table 9). The body of `vertical_guidance` is self-explanatory and similar to the one for Murϕ. It should only be noted that guard `else` is always executable and that expression `skip` leaves the current system state unchanged. Moreover, functions `pitch_event`, `vs_event`, and `vga_event` are spelled out as `inline`s here.

The verification technique we employed in Spin for reasoning about the FGS, namely *assertions*, is similar to the one we used in Murϕ. More precisely, Promela's assertion statement `assert` aborts the state exploration conducted by Spin's verifier whenever its argument expression evaluates to false in some system state associated with the assertion statement. Our specification of the mode confusion properties are depicted in Table 10, where '`!`', '`&&`', and '`||`' stand for the logical connectives *not*, *and*, and *or*, respectively. Moreover, the symbols `/*` and `*/` denote the begin and end of comments. In our specification, `crew_input`, `mode_change`, `ignored_crew_input`, and `indirect_mode_change`, which are defined as Boolean functions in Murϕ, are simply introduced via `#define`s. In order to encode expression `mode_change`, we have to keep a copy of the 'old' values of all global variables of interest, as in the Murϕ model. Stating the mode confusion properties in Spin's version of linear-time logic requires the re-compilation of Spin with compiler option `-DNXT`, such that the next-state operator, which is desired for specifying `mode_change`, becomes available. Although this would have allowed us to proceed as described for SMV, we preferred not to do so. The reason is that Spin does not support the definition of temporal formulas in a modular fashion, i.e., by composing complex formulas from more simpler ones, as SMV does. Thereby, temporal formulas related to mode confusion would be very lengthy and difficult to read. The verification results returned by the Spin verifier are similar to the ones for Murϕ. The Spin model of the FGS also possesses 242 states and 3 388 transitions (+ 1 "dummy" transition). Unfortunately, Spin crashes and core dumps when analyzing the invalid assertions *search for ig-*

Table 9. Specification of module *vertical_guidance* in Spin

```
inline pitch_event(env_ev) { env_ev==vs_pitch_wheel_changed }
inline vs_event(env_ev)    { env_ev==vs_switch_hit }
inline vga_event(env_ev)   { env_ev==ga_switch_hit || ... }
inline vertical_guidance(env_ev)
{ if :: pitch_event(env_ev) ->
        simple_guidance(activate, pitch_mode, pitch_signal);
        if :: pitch_signal==activated ->
                simple_guidance(deactivate,  vs_mode,  vs_signal);
                simple_guidance(deactivate, vga_mode, vga_signal)
           :: else                      -> skip
        fi
     :: vs_event(env_ev) ->
        simple_guidance(switch, vs_mode, vs_signal);
        if :: vs_signal==activated    ->
                simple_guidance(deactivate, pitch_mode, pitch_signal);
                simple_guidance(deactivate,   vga_mode,   vga_signal)
           :: vs_signal==deactivated  ->
                simple_guidance(  activate, pitch_mode, pitch_signal)
           :: else                      -> skip
        fi
     :: vga_event(env_ev) ->
        if :: env_ev==ga_switch_hit   ->
                simple_guidance(switch, vga_mode, vga_signal)
           :: else                      ->
                simple_guidance( clear, vga_mode, vga_signal)
        fi;
        if :: vga_signal==activated   ->
                simple_guidance(deactivate, pitch_mode, pitch_signal);
                simple_guidance(deactivate,    vs_mode,    vs_signal)
           :: vga_signal==deactivated ->
                simple_guidance(  activate, pitch_mode, pitch_signal)
           :: else                      -> skip
        fi
     :: else -> skip
  fi }
```

nored crew inputs and *search for indirect mode changes*. However, it still writes an error trace which can be fed into Spin's simulator. No other violated assertions were detected during the exhaustive state-space search which took under 2 seconds and required about 2.6 MBytes memory on a SUN SPARCstation 20. It should be mentioned that a previous effort to analyze a FGS using Spin suffered from an intractably large state space [15]. That model was then checked for invariants using Spin's *bitstate hashing algorithm*.

Summarizing, carrying out our case study in Spin was feasible but less elegant than in Murϕ due to the lack of procedure and function constructs in Promela, which had to be encoded using inlines and #`define`s. We would like to see a

Table 10. Specification of some *mode confusion properties* in Spin

```
bit old_pitch_mode=cleared; bit old_vs_mode=cleared;
bit old_vga_mode  =cleared;
/* check for response to pressing VS button           */
assert(!(old_vs_mode==cleared) || (vs_mode==active));
assert(!(old_vs_mode==active ) || (vs_mode==cleared));
/* search for ignored crew inputs (property violated)   */
assert(!(crew_input) || mode_change);
/* no unknown ignored crew inputs                      */
assert(!(crew_input && !(ignored_crew_input)) || mode_change);
/* search for indirect mode changes (property violated) */
assert(!(!(crew_input)) || !(mode_change));
/* no unknown indirect mode changes                    */
assert(!(!(crew_input) && !(indirect_mode_change)) || !(mode_change));
/* save the current mode values                        */
old_pitch_mode=pitch_mode;  old_vs_mode=vs_mode;  old_vga_mode=vga_mode;
```

richer type system in Spin, which can handle more than one `mtype` definition. Especially useful to us were Spin's capabilities to simulate Promela models and to feed back error traces into the simulator. Simulations helped us to quickly identify the causes of ignored crew inputs and indirect mode changes. Beside monitoring variables, we found it useful that Spin highlights the part of the Promela description corresponding to the system state under investigation.

6 Discussion

In this section we discuss the strengths and weaknesses of Murϕ, SMV, and Spin regarding their system and property description languages and regarding their capabilities for generating and animating diagnostic information. We restrict our discussion to the observations we made on the FGS case study and refrain from a more general comparison or a comparison along the line of a "feature list." Not only is our experience with the tools limited, but a single case study will inevitably give a biased picture since tools are developed with different objectives and one will be more tailored for an application than another.

The system description languages of all three verification tools allow us to model the deterministic, synchronous behavior of the FGS, as well as the non-deterministic behavior of the system's environment. However, Murϕ's language stands out since it (i) implements numerous language constructs and has a rich type system, as found in imperative programming languages, (ii) supports a modular programming style via parameterized procedures and functions, and (iii) permits one to easily adapt the existing PVS specification of the mode logic [13]. However, SMV's `module` concept is slightly more elegant than Murϕ's procedure concept for our application since mode variables can be declared within the module to which they belong. A major difference between the tools' languages is that Murϕ and Spin allow model encoding using sequential algo-

rithms, whereas SMV requires an algorithm description by parallel assignments. Regarding Promela, one notices that it is designed to specify asynchronous systems. It only offers the process declaration construct `proctype` for encapsulating code fragments. We used `inline` declarations to work around this problem. However, an inline construct is no substitute for a procedure mechanism. Although, depending on the employed parameter mechanism, both constructs may semantically coincide, there is an important practical difference. Inlines may blow-up system descriptions, thereby making, e.g., syntax checks inefficient. We experienced durations of syntax checks well exceeding ten minutes for some variations of our Spin model. Finally, all three tools are missing the ability to organize events in a *taxonomy* via sub-typing. Such a concept would help us to divide all events into lateral-mode and vertical-mode events, and further into Pitch events, HDG events, etc.

Regarding the second issue, we also identified important differences among the tools. Since all mandatory and mode confusion properties of interest are invariants, they can be stated as assertions and verified in state-exploration tools, such as Murϕ, as well as more general model-checking tools, such as SMV and Spin. When specifying mode confusion properties, a temporal logic is most convenient since it allows one to implicitly refer to adjacent states in program paths using the next-state operator. This is important for describing property mode_change which requires one to access the mode variables of adjacent states. In contrast to Murϕ, the encoding of mode confusion properties in SMV does not require the storage of old values of mode variables. Thereby, the size of the associated state vector is cut in half. Spin can be employed both as an assertion checker, similar to Murϕ, and as a model checker, similar to SMV. Especially, SMV's BDD-based model checker performed very well in our case study since mode logics have the characteristics of Boolean terms which can be represented efficiently using BDDs. However, the small state space of our example system precludes us from fairly comparing the run times of Murϕ, SMV, and Spin.

Concerning the third issue, only Spin provides rich features for simulating and animating diagnostic information. Each tool returns an error trace whenever a desired system property is invalidated. Murϕ and SMV output a textual description of the error trace, which displays the global variables assignments at all states of the trace. Spin, however, is able to animate error traces using *message sequence charts*, *time sequence panels*, and *data value panels* which are integrated in its *graphical user interface*, known as `Xspin`. In our case study involving a synchronous system only the data value panel was of use. This feature and the ability to highlight the source code line corresponding to the current state in the simulation enabled us to detect sources of mode confusion quickly.

7 Conclusions and Future Work

This paper advocates the use of state-exploration techniques for analyzing mode confusion. Compared to theorem provers, model-checking tools are able to verify the properties of interest automatically. When weighing the strengths of Murϕ,

SMV, and Spin for our application, it turned out that these are complementary: Murϕ has the most pleasant system description language, including a rich type system; SMV's way of integrating temporal logics supports the convenient specification of mode confusion properties; Spin's capability of animating diagnostic information enables the fast detection of sources of mode confusion.

Regarding future work, our case study should be extended to include more components of today's digital flight decks and, subsequently, to explore other interesting properties related to mode confusion.

Acknowledgments. We thank Ricky Butler and Steve Miller for many enlightening discussions about mode confusion, as well as Ben Di Vito and the anonymous referees for their valuable comments and suggestions.
